Abstract. Meeting internationally agreed-upon climate targets requires carbon dioxide removal (CDR) strategies coupled with an urgent phase-down of fossil fuel emissions. However, the efficacy and wider impacts of CDR are poorly understood. Enhanced rock weathering (ERW) is a land-based CDR strategy requiring large-scale field trials. Here we show that a low $3.44\,t\,ha^{-1}$ wollastonite treatment in an 11.8 ha acid-rain-impacted forested watershed in New Hampshire, USA, led to cumulative carbon capture by carbonic acid weathering of 0.025–$0.13\,t\,CO_2\,ha^{-1}$ over 15 years. Despite a 0.8–$2.4\,t\,CO_2\,ha^{-1}$ logistical carbon penalty from mining, grinding, transportation, and spreading, by 2015 weathering together with increased forest productivity led to net CDR of 8.5–$11.5\,t\,CO_2\,ha^{-1}$. Our results demonstrate that ERW may be an effective, scalable CDR strategy for acid-impacted forests but at large scales requires sustainable sources of silicate rock dust.

1 Introduction

The Intergovernmental Panel on Climate Change (IPCC) (Rogelj et al., 2018) Special Report on global warming indicates large-scale deployment of carbon dioxide removal (CDR) technologies will be required to avoid warming in excess of $1.5\,°C$ by the end of this century. Land-based CDR strategies include enhanced rock weathering (ERW), which aims to accelerate the natural geological process of carbon sequestration by amending soils with crushed reactive calcium (Ca)- and magnesium (Mg)-bearing rocks such as basalt (The Royal Society and The Royal Academy of Engineering, 2018; Hartmann et al., 2013). Forests represent potential large-scale deployment opportunities where rock amendments may provide a range of benefits, including amelioration of soil acidification and provisioning of inorganic plant nutrients to cation-depleted soils (Hartmann et al., 2013; Beerling et al., 2018). Although ERW has not yet been demonstrated as a CDR technique at the catchment scale, a forested watershed experiment at the Hubbard Brook Experimental Forest (HBEF, 43°56′N, 71°45′W) in the White Mountains of New Hampshire, USA, provides an unusual opportunity for assessing proof of concept in this priority research area.
The HBEF watershed experiment, designed to restore soil calcium following decades of leaching by acid rain, involved application of a finely ground rapidly weathered calcium silicate mineral wollastonite ($CaSiO_3$; $3.44\,t\,ha^{-1}$) on 19 October 1999 to an 11.8 ha forested watershed (Likens et al., 2004; Peters et al., 2004; Shao et al., 2016). Unlike the carbonate minerals (e.g. $CaCO_3$) commonly applied to acidified soils (Lundström et al., 2003), wollastonite does not release CO_2 when weathered (Supplement) so is much better suited for CDR (Hartmann et al., 2013). It also has dissolution kinetics comparable to or faster than other calcium-rich sili-

cate minerals such as labradorite found in basalt (Brantley et al., 2008). Thus, the HBEF experiment provides a timely and unparalleled opportunity for investigating the long-term (15 years) effects of ERW on CDR potential via forest and stream-water chemistry responses.

In the case of ERW with wollastonite, CDR follows as Ca cations (Ca^{2+}) liberated by weathering consume atmospheric CO_2 through the formation of bicarbonate (HCO_3^-) by charge balance, as described by the following reaction:

$$CaSiO_3 + 3H_2O + 2CO_2 \rightarrow Ca^{2+} + H_4SiO_4 + 2HCO_3^-. \quad (R1)$$
However, forests in the northeastern USA have experienced acid deposition (Likens and Bailey, 2014), changes in nitrogen cycling (Goodale and Aber, 2001; McLauchlan et al., 2007), and increases in dissolved organic carbon (DOC) fluxes (Cawley et al., 2014) that may affect CO_2 removal efficiency by ERW processes. In particular, CO_2 consumption as measured by bicarbonate production may be diminished if sulfate (SO_4^{2-}), nitrate (NO_3^-), or naturally occurring organic acid (OA) anions (Fakhraei and Driscoll, 2015) (H_2A^-) in DOC intervene to inhibit the following mineral weathering reactions. For example

$$CaSiO_3 + H_2O + H_2SO_4 \rightarrow Ca^{2+} + H_4SiO_4 + SO_4^{2-}, \quad (R2)$$

$$CaSiO_3 + H_2O + 2HNO_3 \rightarrow Ca^{2+} + H_4SiO_4 + 2NO_3^-, \quad (R3)$$

$$CaSiO_3 + H_2O + 2H_3A \rightarrow Ca^{2+} + H_4SiO_4 + 2H_2A^-. \quad (R4)$$

These environmental effects on stream-water chemistry are well documented at the HBEF (Cawley et al., 2014; Likens and Bailey, 2014; Rosi-Marshall et al., 2016; McLauchlan et al., 2007) and may be exacerbated under future climate change (Sebestyen et al., 2009; Campbell et al., 2009).

Here we exploit the experimental design and long-term monitoring of stream-water chemistry, trees, and soils for two small forested HBEF watersheds to evaluate the effects of the wollastonite treatment in 1999 on catchment CO_2 consumption via inorganic and organic pathways. Further, we examine how biogeochemical perturbations in S, N, and organic carbon cycling affect catchment inorganic CO_2 consumption. We consider the forest response, the carbon cost for ERW deployment (mining, grinding, transportation, and application), and the net greenhouse gas balance for the treatment. Finally, we provide an initial assessment of the net CDR potential of silicate treatments deployed over larger areas of acidified forest in the northeastern United States.

2 Methods

This section describes the site and wollastonite treatment (Sect. 2.1) and our approaches for modelling the inorganic carbon fluxes in stream water (Sect. 2.2) and other greenhouse gas fluxes associated with the treatment (Sect. 2.3). The variables from each of the seven equations in Methods are tabulated in Table 1 along with the section, equation, figure, and table numbers where they appear.

2.1 Site and treatment

2.1.1 Site description

The HBEF has a temperate climate with $\sim 1400\,mm$ mean annual precipitation of which up to one-third falls as snow (Campbell et al., 2007). The mean temperatures in January and July are -9 and $18\,°C$ respectively, and the period from mid-May to mid-September comprises the growing season (Campbell et al., 2007). There are six small southeast-facing watersheds in the HBEF (Fig. 1) with 20 %–30 % slopes (Groffman et al., 2006), including one which received the silicate treatment (watershed W1, 11.8 ha, 488–747 m a.s.l.) and a biogeochemical reference (watershed W6, 13.2 ha, 545–791 m a.s.l.). Carbonate and evaporite minerals are in very low abundance (< 1 % calcite in the crystalline rocks and glacial deposits) in these silicate-mineral-dominated watersheds (Johnson et al., 1981). Well-drained Typic Haplorthod soils with pH < 4.5 and mean depth of 0.6 m formed from relatively impermeable glacial till, which restricts water flow and protects the underlying schist bedrock from weathering. Overland runoff and flow through bedrock are both thought to be negligible (Likens, 2013). Hydrologically, the HBEF watersheds are typical of small catchments in northern New England (Sopper and Lull, 1965). Flow rates for W1 and W6 along with stream-water pH are shown in Fig. S1 in the Supplement. Prior to treatment, stream-water calcium concentrations were under $30\,\mu mol\,L^{-1}$ while bicarbonate concentrations were under $5\,\mu mol\,L^{-1}$, below the ranges for typical world rivers (Moon et al., 2014) (60–2293 $\mu mol\,Ca^{2+}\,L^{-1}$, 179–4926 $\mu mol\,HCO_3^-\,L^{-1}$).

Fagus grandifolia Britt., *Betula alleghaniensis* Ehrh., and *Acer saccharum* Marsh. are the dominant trees in this northern hardwood forest, while *Betula papyrifera* Marsh., *Abies balsamea* (L.) Mill., and *Picea rubens* Sarq. are common at the highest elevations where soils tend to be shallow and wetter (Cho et al., 2012). *A. saccharum* and *P. rubens* are both calcium-sensitive, but soil calcium-bearing minerals are less available to *A. saccharum* (Blum et al., 2002), and total bioavailable calcium content decreases with elevation (Cho et al., 2012). This silicate-addition experiment was designed to replace bioavailable calcium which had been stripped from the soils by decades of acid deposition.

2.1.2 Treatment description

On 19 and 21 October 1999, W1 was treated with $344\,g\,m^{-2}$ of pelletized wollastonite ($CaSiO_3$) by a GPS-equipped helicopter with a motorized spreader to ensure even deployment across the catchment, including the 1804 m^2 streambed (Peters et al., 2004). Following treatment, the lignin-sulfonate binder forming the pellets dissolved within several days (Peters et al., 2004), and the ground wollastonite itself dissolved rapidly in the upper Oie soil horizon, increasing Oie base saturation from 40 % to 78 % and raising soil pH from 3.88 to

Table 1. Summary of variables presented in Methods (Sect. 2, Eqs. 1 through 7).

Variable	Units	Sections	Equations	Figures	Tables	Description
$[HCO_3^-]$	$mol\,kgw^{-1}$	2.2.3, 2.2.4	(1), (3)	2a, S5a, d, g, S6a		Concentrations of solutes in water, in this case HCO_3^-, are denoted by square brackets.
t	time	2.2.3–5	1–5			Denotes individual samples in the time series
α_{rain,HCO_3}	fraction	2.2.3, 2.2.4, Appendix A	(1), (2), (A2)	S3		Fraction of an ion, in this case HCO_3^-, originating from precipitation.
flow	$mm\,yr^{-1}$	2.2.3–5	(1)–(5)	S2d		Stream-water flow
CO_{2,HCO_3}	$mol\,C\,yr^{-1}$	2.2.3, 2.2.4	(1), (3)	2b, S5b, e, h	3, S1	Total watershed CO_2 consumption as calculated from bicarbonate
$CO_{2,ions}$	$mol\,C\,yr^{-1}$	2.2.3	(2)		3	Total watershed CO_2 consumption as calculated from major ions
$Wo\text{-}CO_{2,HCO_3}$	$mol\,C\,yr^{-1}$	2.2.4	(3)	2c,5, S5c, f, i, S6b, c	3, 4, S1	Watershed CO_2 consumption as calculated from bicarbonate resulting from wollastonite weathering. Our conservative/pessimistic ΔCONS estimate in our GHG balance is the 15-year sum.
X_{Ca}	fraction	2.2.3, Appendix B	(3), (4), (B1)	S1a		Fraction of total calcium originating from wollastonite
$Wo\text{-}CO_{2,Ca}$	$mol\,C\,yr^{-1}$	2.2.3	(4)	2f, S6b, c	3, S1	Watershed CO_2 consumption as calculated from calcium due to wollastonite weathering. Our optimistic estimate for ΔCONS in our GHG balance is the 15-year sum.
C_i	$mol\,kgw^{-1}$	2.2.5	(5)			Concentration of solute for sample i (collected approximately monthly for chemical analysis)
Q_i	$mm\,time^{-1}$	2.2.5	(5)			Streamflow for sample i
Q_k	$mm\,d^{-1}$	2.2.5	(5)	S2b		Streamflow for day k
N	number	2.2.5	(5)			Number of daily flow measurements
ΔGHG	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Net treatment effect on watershed greenhouse gas balance
Δwood	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Treatment effect on woody biomass over 10 years: positive if wood production increases relative to reference watershed.
ΔCH4	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Treatment effect on soil CH_4 sink since 2002: positive if the soil CH_4 sink increases relative to reference watershed.
ΔSRESP	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Treatment effect on soil CO_2 emissions since 2002: positive if emissions decrease relative to reference watershed.
ΔCONS	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Treatment effect on CO_2 consumption over 15 years: ranges from $Wo\text{-}CO_{2,HCO_3}$ to $Wo\text{-}CO_{2,Ca}$
ΔN2O	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Treatment effect on soil N_2O emissions since 2002: positive if emissions decrease relative to reference watershed.

Table 1. Continued.

Variable	Units	Sections	Equations	Figures	Tables	Description
ΔNO3N2O	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Treatment effect on downstream N_2O emissions (due to nitrate export) over 15 years: positive if emissions decrease relative to reference watershed.
ΔDOC	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Treatment effect on dissolved organic carbon export over 15 years: positive if export decreases relative to reference watershed. This represents carbon loss from the watershed and likely CO_2 emissions downstream.
LOGPEN	$t\,CO_2\,ha^{-1}$	2.3.1	(6)	5	4	Logistical emissions penalty associated with mining, milling, pelletization, transport, and application of the wollastonite treatment, expected to be negative.
s	$m^2\,kg^{-1}$	2.3.3	(7)			Specific surface area of material being milled
e_p	$kJ\,kg^{-1}$	2.3.3	(7)			Specific potential energy of material being milled
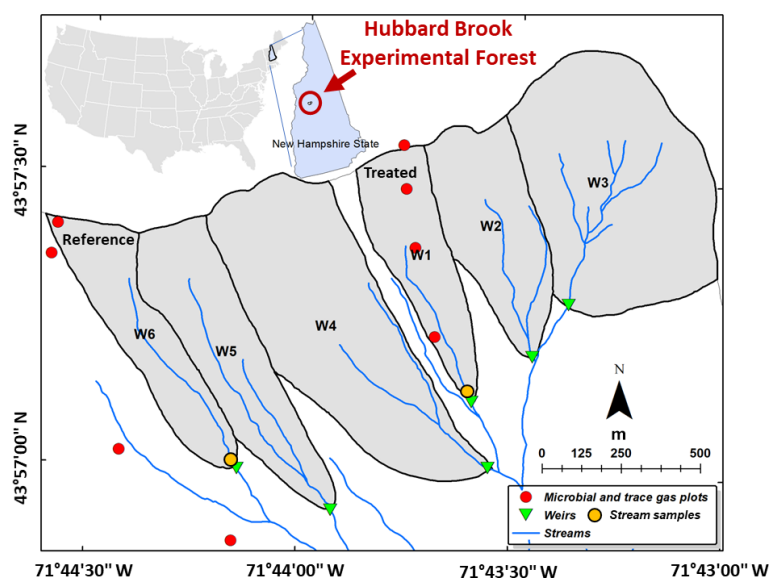

Figure 1. Location of the sampling sites and experimental watersheds. Our stream-water samples were collected just upstream of the weirs in the treated and reference watersheds (gold discs), and our trace gas samples were collected at different elevations in treated (W1) and untreated (W6) forests (red discs).

4.39 within 1 year (Johnson et al., 2014). Although the budget of wollastonite-derived calcium (Wo-Ca) has never been closed due to lack of data from vegetation and from deeper soil layers (Shao et al., 2016), it is thought that uptake by vegetation and retention by soil exchange sites delayed transport of Wo-Ca to lower soil horizons and stream water for 3 years (Johnson et al., 2014).

2.2 Geochemical modelling and CO_2 consumption fluxes

CO_2 consumption, the CDR pathway most closely associated with ERW, can be calculated from concentrations of either bicarbonate or the base cations released during weathering (Reaction R1). These two approaches may provide different answers if bicarbonate is reduced in the presence of other acids (Reactions R2–R4). To calculate bicarbonate-derived CO_2 consumption, we must model the speciation of dis-

solved inorganic carbon (DIC). This depends on two variables which must also be modelled because we do not have a time series: stream-water $p\mathrm{CO_2}$ and stream-water temperature. We then calculate total catchment $\mathrm{CO_2}$ consumption fluxes and treatment effects, taking care to account for differences in sampling frequency between chemistry samples and water flow measurements.

2.2.1 Forward modelling of stream-water chemistry including dissolved inorganic carbon

We used a forward modelling approach to calculate dissolved stream-water bicarbonate concentrations ($[\mathrm{HCO_3^-}]_{\mathrm{stream}}$) in the treated and reference watersheds (Fig. 1) over ~ 25 years, including 15 years post-treatment, with the United States Geological Survey (USGS) aqueous geochemistry software PHREEQC version 3.3.12-12704 (Parkhurst and Appelo, 1999) and monthly long-term (1992–2014) stream-water (Driscoll, 2016b, a) and rain and snow precipitation (Likens, 2016b, a) chemistry measurements.

Using MATLAB (version R2016a) scripts, we wrote PHREEQC input files and determined the inorganic carbon species for each stream-water sample with PHREEQC. Along with a standard database which decouples ammonium and nitrate (Amm.dat, provided with the PHREEQC software), we included the ionization constants for the organic acid triprotic analogue and the constants for Al complexation described for Hubbard Brook streams (Fakhraei and Driscoll, 2015) in our PHREEQC simulations. These are $\mathrm{pK_{a1}} = 2.02$, $\mathrm{pK_{a2}} = 6.63$, $\mathrm{pK_{a3}} = 7.30$, $\mathrm{pK_{Al1}} = 4.07$, $\mathrm{pK_{Al2}} = 7.37$, $\mathrm{pK_{Al3}} = 6.65$, and site density $m = 0.064$ mol sites $\mathrm{mol\,C^{-1}}$. Our organic acid concentrations are the product of the corresponding site density of reactions and the measured dissolved organic carbon concentration (Fakhraei and Driscoll, 2015); these were PHREEQC inputs along with total monomeric Al and major ion concentrations from the longitudinal datasets.

Spectator ions ($\mathrm{Cl^-}$ and $\mathrm{NH_4^+}$) were adjusted to achieve charge balance given the measured pH for the treated and reference watersheds. $\mathrm{Cl^-}$ was only adjusted when charge balance was not achieved using $\mathrm{NH_4^+}$ alone. This was deemed to be the case when PHREEQC failed to converge or when the percent error exceeded 5 %. We used original rather than adjusted rainwater Cl to calculate the contribution of rainwater to stream-water chemistry (described below). These adjusted ions were then held constant for our modelled scenarios, while pH was allowed to vary.

Exploratory PHREEQC tests (charge balancing on DIC) either with or without organic acids suggest that the acids depress total DIC, $\mathrm{HCO_3^-}$, and also the saturation state of gaseous $\mathrm{CO_2}$. Similar variability in the saturation is also observed when DIC values from partially degassed samples from the streams are used as input. We chose minimum and maximum values of 1100 and 1700 ppm, or ~ 3 and 4.6×368, the mean value of Mauna Loa $p\mathrm{CO_2}$ (Tans

and Keeling, 2017) for 1985–2012. These values correspond to $\log_{10}(p\mathrm{CO_2(g)}) = -2.87 \pm 0.09$ SD derived from a prior analysis of this variability for the same time range (Fakhraei and Driscoll, 2015).

2.2.2 Stream-water temperature

Air temperatures for the Hubbard Brook watersheds (Campbell, 2016) were converted to stream-water temperatures (Mohseni and Stefan, 1999). Rainwater temperatures were set equal to stream-water temperatures. These temperatures were used in our PHREEQC modelling, with equilibrium constants for the DIC species as functions of temperature. Only samples measured closest to the weirs and with a valid pH were processed with PHREEQC.

2.2.3 Total catchment $\mathrm{CO_2}$ consumption

We calculate total annual watershed $\mathrm{CO_2}$ consumption (Reaction R1) as the product of stream-water flow and stream-water bicarbonate concentration $[\mathrm{HCO_3^-}]$ at time t corrected for the $\mathrm{HCO_3^-}$ contribution from rainwater ($\alpha_{\mathrm{rain, HCO3}}(t)$, Appendix A):

$$\mathrm{CO_{2,HCO_3}}(t) = \left(1 - \alpha_{\mathrm{rain, HCO_3}}(t)\right)[\mathrm{HCO_3^-}](t) \times \mathrm{flow}(t), \quad (1)$$

where $[\mathrm{HCO_3^-}](t)$ is given in $\mathrm{mol\,kgw^{-1}}$ and $\mathrm{flow}(t)$ is the "runoff" in $\mathrm{mm\,yr^{-1}}$. Calculated $[\mathrm{HCO_3^-}]$ and annual $\mathrm{CO_2}$ consumption for the treated and reference watersheds (Eq. 1) comprise our baseline simulations and represent a primary test of hypothesized increased carbon capture resulting from weathering of the applied silicate.

Bicarbonate-derived $\mathrm{CO_2}$ consumption (Eq. 1) is the most conservative approach to estimating net carbon fluxes related to ERW. For natural freshwaters in equilibrium with the atmosphere, this entails a titration for total alkalinity with a possible correction for the concentration of organic acid anions (Köhler et al., 2000). However, another widely used (Jacobson and Blum, 2003) measure of $\mathrm{CO_2}$ consumption is derived by assuming that any base cations ($\mathrm{Ca^{2+}}$, $\mathrm{Mg^{2+}}$, $\mathrm{K^+}$, and $\mathrm{Na^+}$) released from minerals will be charge-balanced by bicarbonate formation in the oceans:

$$\begin{aligned} \mathrm{CO_{2,ions}}(t) = \Big(&2[\mathrm{Ca^{2+}}]\left(1 - \alpha_{\mathrm{rain, Ca}}(t)\right) \\ &+ 2[\mathrm{Mg^{2+}}]\left(1 - \alpha_{\mathrm{rain, Mg}}(t)\right) \\ &+ [\mathrm{K^+}]\left(1 - \alpha_{\mathrm{rain, K}}(t)\right) \\ &+ [\mathrm{Na^+}]\left(1 - \alpha_{\mathrm{rain, Na}}(t)\right) - 2[\mathrm{SO_4^{2-}}](t)\Big) \\ &\times \mathrm{flow}(t), \end{aligned} \quad (2)$$

where the term $-2[\mathrm{SO_4^{2-}}](t)$ represents a commonly applied correction for sulfuric acid weathering (Chetelat et al., 2008) (Reaction R2). Contributions from precipitation such as $\alpha_{\mathrm{rain, Ca}}(t)$ are calculated by replacing bicarbonate with the individual base cation in Eq. (A2). We tabulate $\mathrm{CO_{2,ions}}(t)$ results for comparison with $\mathrm{CO_{2,HCO_3}}(t)$ below.

2.2.4 Response of CO_2 consumption to treatment

To isolate a treatment effect for bicarbonate, we used strontium isotopes as a tracer of wollastonite (Wo) weathering within a previously published mixing function (Nezat et al., 2010; Peters et al., 2004) (Appendix B, Fig. S3). This mixing function provides the fraction X_{Ca} of calcium originating from wollastonite (Eq. B1). We remove the contribution of all mineral sources other than wollastonite to CO_2 consumption (Eq. 1), which is simulated with Ca^{2+} concentrations reduced by $(1 - X_{Ca})$:

$$
\begin{aligned}
\text{Wo-CO}_{2,\text{HCO}_3}(t) = {} & \text{CO}_{2,\text{HCO}_3}(t) \\
& - \Big\{ [\text{HCO}_3^-]\Big(t, (1 - X_{Ca})[\text{Ca}^{2+}]\Big) \\
& \times \big(1 - \alpha_{\text{rain},\text{HCO}_3}(t)\big) \times \text{flow}(t) \Big\},
\end{aligned} \tag{3}
$$

which effectively provides a lower limit on the treatment effect.

We can also derive an upper limit for the treatment effect from Reaction (R1). For an ERW treatment, transient changes in the export of ions not derived from the applied minerals may occur, but we consider that the cations released from the applied minerals comprise the most unambiguous treatment effect in our study. The charge associated with wollastonite-derived Ca^{2+} (Wo-Ca) determines the CO_2 consumption associated with the HBEF wollastonite treatment. Our optimistic treatment effect based on calcium rather than bicarbonate is

$$
\text{Wo-CO}_{2,\text{Ca}}(t) = 2 \times X_{Ca} \times [\text{Ca}^{2+}](t) \times \text{flow}(t). \tag{4}
$$

Equations (3) and (4), together with our flux calculations accounting for sparsity of concentration data compared to daily flow data (Sect. 2.2.5), should help avoid major uncertainties in catchment-scale CO_2 consumption calculations: the provenance of the cations and variations in concentration and discharge (Moon et al., 2014).

2.2.5 Flux calculations

To ensure that fluxes from our two watersheds were comparable and to correct for the sparsity of solute measurements compared to flow measurements, we created rolling annual flow-adjusted fluxes using Method 5 of Littlewood et al. (1998) at five evenly spaced points each year:

$$
\text{flux} = \text{scale} \times \left[\frac{\sum\limits_{i=1}^{M} C_i Q_i}{\sum\limits_{i=1}^{M} Q_i} \right] \times \left[\frac{\sum\limits_{k=1}^{N} Q_k}{N} \right], \tag{5}
$$

where Q_i is the measured instantaneous stream flow, C_i is the concentration for sample i, M is the number of stream-water chemistry samples in the year (usually 12), Q_k is the

kth flow measurement, and N is the number of flow measurements. In our case, daily flow measurements (Campbell, 2015) and approximately monthly stream-water samples (Driscoll, 2016b, a) were available. Therefore, the mean concentration for the preceding 12 months is multiplied by the mean flow for the same period, suitably scaled to get the total annual flux. Without sub-daily timestamps for the longitudinal stream-water chemistry data, we used daily total flows rather than instantaneous flows. Tests suggested that there was little difference between using mean daily instantaneous flows and the mean daily total flows.

2.3 Greenhouse gas balance

The success of any treatment for climate change mitigation is determined by the net greenhouse gas (CO_2 equivalent) fluxes prior to and following treatment, at the treatment site and downstream. In addition to increased CO_2 consumption, desirable outcomes for a treatment include increased ecosystem carbon storage in biomass and soils and decreases in ecosystem, downstream, and logistical greenhouse gas emissions.

2.3.1 Greenhouse gas budget for the wollastonite treatment

At the HBEF, we have measured the CO_2 consumption due to the wollastonite treatment in two different ways and these determine our range of values to be incorporated in our greenhouse gas (GHG) budget. Several other treatment effects can be estimated relative to the reference watershed, but some aspects of the total GHG balance are missing. For example, we have measurements of soil respiration (root + heterotrophic) and dissolved organic carbon (DOC) export in stream water, but we lack measurements of canopy respiration from leaves and stems and export of particulate organic carbon in stream water. Our partial greenhouse gas budget for the HBEF wollastonite treatment will therefore be given by

$$
\begin{aligned}
\Delta \text{GHG} = {} & \Delta \text{wood} + \Delta \text{SRESP} + \Delta \text{CH4} + \Delta \text{N2O} \\
& + \Delta \text{CONS} + \Delta \text{NO3N2O} + \Delta \text{DOC} \\
& + \text{LOGPEN},
\end{aligned} \tag{6}
$$

where our partial GHG treatment effect (ΔGHG) is the sum of greenhouse gas sink and source responses. Measured sinks for the wollastonite experiment include biomass in wood (Δwood), CO_2 consumption (ΔCONS), and a soil sink for methane (ΔCH4). Sources include N_2O emissions from both soil (ΔN2O) and exported nitrate (ΔNO3N2O) and CO_2 emissions from soil respiration (ΔSRESP), exported dissolved organic carbon (ΔDOC), and logistical operations (LOGPEN).

Sink effects are defined as positive if the sink increases and are given by the difference (treated $-$ reference) between the two watersheds, whereas source effects are defined as

positive for reductions in greenhouse gas emissions (reference − treated). With these definitions, penalties are negative and reduce ΔGHG in Eq. (6). Logistical emissions and CO_2 consumption due to weathering of applied wollastonite are zero for the reference watershed, so we expect LOGPEN to be negative and ΔCONS to be positive.

Wood is a longer-term carbon sink than leaves or twigs so we have chosen to let this represent our biomass increment. Equation (6) neglects ecosystem disturbances including fire and possible carbonate mineral precipitation in soils. There is no evidence for the latter at the HBEF.

We used a range of emissions factors for N_2O to estimate the penalty associated with nitrate export (ΔNO3N2O); low: $0.0017\,kg\,N_2O\text{-}N\,kg^{-1}$ DIN (Hu et al., 2016) and high: $0.0075\,kg\,N_2O\text{-}N\,kg^{-1}$ DIN (De Klein et al., 2006), where DIN is dissolved inorganic nitrogen dominated by nitrate. This N_2O was then converted to CO_{2e} (CO_2 equivalents in terms of cumulative radiative forcing) given the 100-year time horizon global warming potential (Pachauri et al., 2014) (GWP_{100}) for N_2O: $265\,g\,CO_{2e}\,g^{-1}\,N_2O$. Likewise, ΔCH4 was converted to CO_{2e} (CO_2 equivalents in terms of cumulative radiative forcing) given GWP_{100} for CH_4: $28\,g\,CO_{2e}\,g^{-1}\,CH_4$.

2.3.2 Carbon sequestration in wood

We calculate our treatment effect on wood production as the difference between the treated and reference watershed mean wood production (Battles et al., 2014) over two 5-year periods. We considered these differences (treated − reference) to be an estimate of the treatment effect on potentially long-term (decades to centuries) biomass carbon sequestration. Assuming 46.5 % of the woody biomass is carbon (Martin et al., 2018), our calculated cumulative additional C sequestration in the treated watershed over 10 years was $20.7\,mol\,C\,m^{-2}$ ($9.1\,t\,CO_2\,ha^{-1}$). Our optimistic and pessimistic values are derived from the 95 % confidence intervals for the 5-year mean values (Battles et al., 2014).

2.3.3 Greenhouse gas emissions from soils

Measurements (Groffman, 2016) were taken at four elevations in the treated watershed and at points just west of the reference watershed starting in 2002 (Fig. 1). Gas samples were collected from chambers placed on three permanent PVC rings at each of these eight sites (Groffman, 2016). The data were not normally distributed so were analysed with Kruskal–Wallis tests at the 0.05 significance level; however, tests with one-way ANOVA produced the same overall results. All analyses were done in MATLAB R2016a.

Cumulative curves for each of the 24 chambers were generated by matching the dates of the measurements, excluding points which were missing data for any chamber and allowing up to a week's discrepancy between catchments. Nearly all discrepancies were within 1 d. Assuming diurnal

variation was minor compared to seasonal variation, each datum ($g\,C\,m^{-2}\,h^{-1}$) was multiplied by 24 h and by 30 d to get $g\,C\,m^{-2}$ per month. There was no extrapolation to fill gaps in the dataset; results are internally consistent but not comparable to other datasets. We were particularly interested in the elevation-specific responses, as the different elevations have distinct tree species compositions and below-ground responses to the wollastonite treatment (Fahey et al., 2016).

The HBEF experimental watersheds are divided into 25×25 m plots on slope-corrected grids. Vegetation has been surveyed four times since the late 1990s and assigned a zone designation in each plot (Driscoll et al., 2015a, b; Battles et al., 2015b, a) (Fig. S12). To estimate the respiration savings over the whole watershed, we added the areas of individual plots which were assigned to our four vegetation types (low, middle, and high hardwoods and spruce–fir). Because there were seven vegetation types in the datasets, we compared all types with pairwise Kruskal–Wallis tests at the 0.05 significance level using the basal area data for the six dominant tree species. Kruskal–Wallis tests were appropriate because the data, and therefore the differences from the means (residuals), were not normally distributed. These tests suggested that the "extra" vegetation types ("birch–fern glade" and "poor hardwoods" at high elevations and mid-elevations) could be combined with spruce–fir and high and middle hardwoods respectively. Watershed fractions for our combined forest types were 0.155 for spruce–fir, 0.16 for high hardwoods, 0.415 for middle hardwoods, and 0.27 for low hardwoods. When creating our composite treatment effects for the entire watershed, we considered a treatment effect to be present only where our statistical analyses suggested significantly different fluxes.

2.3.4 Logistical carbon emissions costs

We used the 1999 upstate New York CO_2 emission factor for electricity generation from oil (United States Environmental Protection Agency, 1999) ($0.9\,Mg\,CO_2\,MWh^{-1}$) and rearranged Eq. (28) of Stamboliadis et al. (2009):

$$e_p = \frac{\left[e^{\frac{(\ln s/\alpha)}{\mu}}\right]}{3600 \times 1000}, \tag{7}$$

where the specific surface area s ($1600\,m^2\,kg^{-1}$ for our treatment) is related to the specific potential energy e_p of the material ($kJ\,kg^{-1}$), with theoretical parameters (Stamboliadis et al., 2009) $\alpha = 139\,m^2\,kJ^{-1}$ and $\mu = 0.469$ (dimensionless). We convert this potential energy to $MWh\,t^{-1}$ Qz ($3600\,s\,h^{-1}$ and $1000\,kWh\,MWh^{-1}$). The equation was derived for quartz (Qz) which has hardness 7. Because wollastonite hardness is in the range 5–5.5, this equation may overestimate the energy needed to grind the wollastonite.

The main energy source in Allerton will have been coal, and the 1999 Illinois emissions factor (United States Environmental Protection Agency, 1999) is $1.1\,Mg\,CO_2\,MWh^{-1}$.

The monetary cost is USD $0.041\,\mathrm{kWh^{-1}}$ for pelletization of limestone fines and USD $0.85\,\mathrm{t^{-1}}$ product, so we estimate $20.73\,\mathrm{kWh\,t^{-1}}$ product.

Road transport distances were estimated using Google Maps (1397 km from Gouverneur to Allerton, 1757 km from Allerton to Woodstock, 408 km from Gouverneur to Woodstock). We used standard emissions ranges (Sims et al., 2014) for heavy-duty vehicles (HDVs) (70–190 $\mathrm{g\,CO_2\,km^{-1}\,t}$ per rock) and for short-haul cargo aircraft (1200–2900 $\mathrm{g\,CO_2\,km^{-1}\,t^{-1}}$). Calculation details are given in Table 2. The MATLAB script used for these calculations is available on request. Note that t refers to megagrammes, not US short tons.

3 Results

3.1 Wollastonite treatment increased stream-water CO_2 export

We first consider the time series of stream-water changes in Ca^{2+} concentrations in the treated ($[Ca]_{Treated}$) and reference ($[Ca]_{Ref}$) watersheds. Immediately after treatment, $[Ca]_{Treated}$ increased from < 30 to $\sim 60\,\mathrm{\mu mol\,L^{-1}}$ and then slowly declined over the next decade, remaining persistently above $[Ca]_{Ref}$ for 15 years (Fig. 2a). The initial post-treatment peak represents dissolution of wollastonite within the stream (Peters et al., 2004) and release of calcium from hyporheic exchange during the first few years (Shao et al., 2016; Nezat et al., 2010). Retention of Ca^{2+} ions liberated by wollastonite dissolution (Wo-Ca) in the watershed soils (Nezat et al., 2010) and sequestration into tree biomass (Balogh-Brunstad et al., 2008; Nezat et al., 2010) delayed appearance in stream water for 3 years (Shao et al., 2016; Nezat et al., 2010). Subsequently, $[Ca]_{Treated}$ remained approximately double $[Ca]_{Ref}$, with a $\sim 30\,\%$ contribution from non-wollastonite Ca^{2+} until 2012. Towards the end of the time series, increased seasonal NO_3^- export in the treated watershed between 2012 and 2014 (Rosi-Marshall et al., 2016) led to Wo-Ca displacing non-Wo-Ca from the soil exchanger.

We derived the annual export of Ca^{2+} from the treated and reference watersheds as the product of mean annual flow-adjusted Ca^{2+} stream-water concentrations and annual flow (Fig. 2b) (Methods). After accounting for variations in flow, increased stream-water Ca^{2+} concentrations in the treated watershed are translated into a 2-fold increase in total Ca^{2+} export relative to the reference watershed that was maintained for 15 years until 2015 through this analysis period. Overall, the wollastonite treatment resulted in a sharp spike in calculated CO_2 consumption (Wo-$CO_{2,Ca}$) that decreased but remained elevated as a result of the treatment (Fig. 2c).

Temporal patterns in modelled stream-water bicarbonate concentration in both treated and reference watersheds (Fig. 2d), and the corresponding total annual CO_2 consumption (CO_{2,HCO_3}) (Fig. 2e) and CO_2 consumption result-

ing from treatment (Wo-CO_{2,HCO_3}) (Fig. 2f), largely mirror changes in stream-water Ca^{2+} concentrations but are modified by the supply and loss of anions. Calculated flow-adjusted CO_2 consumption (Fig. 2e) peaked 2–3 years post-treatment with a broader peak in CO_2 consumption evident in 2007–2012 corresponding to declining legacy effects of acid rain until transient NO_3^- peaks appeared 2012–2015. Wo-CO_{2,HCO_3} shows a pattern that mirrors Wo-$CO_{2,Ca}$ but is generally 5 times lower (Fig. 2c, f).

3.2 Sulfuric, nitric, and organic acids reduce CDR

We next undertook sensitivity analyses to investigate the effects of acid deposition, increased NO_3^-, and organic acid export from the treated watershed on bicarbonate concentrations and resulting CO_2 consumption (Fig. S5). In a "low-SO_4" scenario (Fig. S5a–c), we sought to understand the effects of acid deposition by replacing the mean monthly time series of stream-water and rainwater SO_4^{2-} for the treated watershed with a new time series (purple curve, Fig. S5a) created by repeating the post-2010 datasets, which reflect diminished acid deposition following emission controls from the US Clean Air Act (Likens and Bailey, 2014). Removing acid rain effects in this manner dramatically increased the calculated bicarbonate concentrations and total annual CO_2 consumption (CO_{2,HCO_3}), increasing the initial spikes resulting from the wollastonite treatment in both by at least 4-fold (purple curves, Fig. S5b, c). An additional legacy of acidification in North American forests (Harrison et al., 1989) is SO_4^{2-} retention on soil clay mineral Fe and Al oxides (Fuller et al., 1987), which were subsequently released by increased soil pH following wollastonite weathering (Shao et al., 2016; Fakhraei et al., 2016). To assess the effect of this legacy SO_4^{2-}, we ran simulations for the treated watershed substituting the lower stream-water SO_4^{2-} concentrations from the reference watershed (T REF, green curves, Fig. S5b, c). Results suggest that legacy SO_4^{2-} accounts for over half of the total acid deposition effect on increased $[HCO_3^-]$ and CO_2 consumption in the simulations.

In the "ref NO_3" scenario (Fig. S5d–f), seasonal spikes in stream-water export of NO_3^- recorded from the treated watershed between 2012 and 2015 were removed by substituting the reference watershed stream-water NO_3^- concentration measurements lacking these spikes. This manipulation markedly increased modelled bicarbonate (Fig. S5e) and mean annual CO_2 consumption (Fig. S5f). To quantify the effects of organic acids on bicarbonate production in the treated watershed, we ran "+OA" and "−OA" simulations, i.e. with and without accounting for organic acids respectively (Fig. S5g–i). Results showed that removing OA from our simulations also increased modelled stream-water bicarbonate concentration (Fig. S5h), and resulting CO_2 consumption (Fig. S5i), in the treated watershed.

**Table 2.** Logistical penalty calculations for the Hubbard Brook wollastonite treatment.

Penalty element	Value and calculation with units
Mass of wollastonite ($CaSiO_3$) shipped to Allerton (t^a Wo)	109665 lbs or 49.7432073 t Wo
Mass of pellets shipped from Allerton (t pellets)	112992 lbs or 51.2523091 t pellets
Ratio of pellet mass to Wollastonite mass	1.0368 = 51.25 t pellets / 49.74 t Wo
HDV transport distance (km)	3154 km = 1397 km (Gouverneur to Allerton) + 1757 km (Allerton to Woodstock)
Transport distance for "local pelletization" calculation (km)	408 km (Gouverneur to Woodstock)
Optimistic transport emissions (g CO_2 g^{-1} Wo applied)	0.229 g CO_2 g^{-1} Wo applied = 70 g CO_2 km^{-1} shipped t^{-1} shipped × ((1397 km × 49.74 t Wo shipped) + (1757 km × 51.25 t pellets shipped)) / 48.86 × 10^6 g Wo applied
Pessimistic transport emissions (g CO_2 g^{-1} Wo applied)	0.620 g CO_2 g^{-1} Wo applied = 190 g CO_2 km^{-1} shipped t^{-1} shipped × ((1397 km × 49.74 t Wo shipped) + (1757 km × 51.25 t pellets shipped)) / 48.86 × 10^6 g Wo applied
Mass of pellets deployed by helicopter (t pellets applied)	110992 lbs or 50.3451243 t pellets applied
Mass of wollastonite deployed by helicopter (t Wo applied)	48.86 t Wo applied = 50.345 t pellets applied / 1.03684
Total area treated (ha)	14.2 ha = 11.8 ha watershed plus 2.4 ha "destructive area" along the western edge
Nominal mean round trip flight distance (km, Woodstock to watershed and back)	5 km
Number of flights (1 short ton hopper capacity)[b]	55.5 = 50.345 t pellets / 0.907 t per trip
Molar mass of wollastonite $CaSiO_3$ (g Wo mol^{-1} Wo)	116.17 g Wo mol^{-1} Wo = 40.08 g Ca mol^{-1} Ca + 28.09 g Si mol^{-1} Si + 3 × 16 g O mol^{-1} O
Molar mass of CO_2 (g CO_2 mol^{-1} CO_2)	44.01 g CO_2 mol^{-1} CO_2 = 2 × 16 g O mol^{-1} O + 12.01 g C mol^{-1} C
Optimistic spreading emissions (mol CO_2 ha^{-1})	483.36 mol CO_2 ha^{-1} = 1200 g CO_2 km^{-1} t^{-1} × 5 km × 50.345 t pellets / 44.01 g CO_2 mol^{-1} CO_2 / 14.2 ha
Optimistic spreading emissions (g CO_2 g^{-1} Wo)	0.006 g CO_2 g^{-1} Wo = 1200 g CO_2 km^{-1} t^{-1} × 5 km × 50.345 t pellets / 48.86 / 10^6 g Wo
Pessimistic spreading emissions (mol CO_2 ha^{-1})	1168.1 mol CO_2 ha^{-1} = 2900 g CO_2 km^{-1} t^{-1} × 5 km × 50.345 t pellets / 44.01 g CO_2 mol^{-1} CO_2 / 14.2 ha
Pessimistic spreading emissions (g CO_2 g^{-1} Wo)	0.015 g CO_2 g^{-1} Wo applied = 2900 g CO_2 km^{-1} t^{-1} × 5 km × 50.345 t pellets / 48.86 × 10^6 g Wo applied

[a] Megagrammes or metric tons, not short tons. [b] Number of flights does not explicitly enter into penalty calculations because the emissions for short-haul aircraft are multiplied by the 5 km round trip distance and the entire mass transported, rather than the mass transported during one round trip (one short ton).

3.3 Effects of increasing wollastonite treatment

Because the HBEF application rate (3.44 t ha^{-1}) is smaller than the 10–50 t ha^{-1} suggested for ERW strategies (Strefler et al., 2018; Beerling et al., 2018), we simulated the possible effects of a 10-fold increase in the stream-water Ca^{2+} concentrations on bicarbonate production (Fig. S6a) and CO_2 consumption (Fig. S6b). In this initial assessment, we assume stream-water responses are directly proportional to wollastonite application rate, i.e. 34.4 t ha^{-1}, and that all other variables remained unchanged. Results show that after 15 years, cumulative Wo-CO_{2,HCO_3} is 73 % of Wo-$CO_{2,Ca}$ (Fig. S6c), as opposed to less than 20 % for the actual rate of 3.44 t ha^{-1} (Table 3). These results suggest that at higher application
Figure 2. Inorganic CO_2 capture at the Hubbard Brook Experimental Forest. **(a)** Observed calcium and **(b)** calcium export in the reference (grey) and treated (blue) watersheds along with the contribution from sources other than wollastonite (red) and the time of treatment (vertical dotted line). **(c)** Calculated CO_2 consumption due to the treatment (Wo-$CO_{2,Ca}$, Eq. 9). **(d)** Modelled stream-water bicarbonate, **(e)** CO_2 consumption (CO_{2,HCO_3}, Eq. 5), and **(f)** CO_2 consumption due to the treatment (Wo-CO_{2,HCO_3}, Eq. 7); colours as for calcium. Simulations **(d–f)** account for the presence of organic acids (+OA). All calcium export **(b)** and CO_2 consumption curves **(c, e, f)** were calculated with flow-normalized concentrations and corrected for sparsity of samples (Methods).

rates of wollastonite, the details of the CO_2 consumption calculations become less important.

3.4 Amplification of organic carbon sequestration by wollastonite treatment

In reversing long-term Ca^{2+} depletion of soils, the silicate rock treatment significantly increased forest growth and wood production between 2–12 years post-treatment relative to the reference watershed (Battles et al., 2014). This forest response increased total carbon sequestration by 20.7 mol C m^{-2} or 9.1 t CO_2 ha^{-1} during those 10 years as a result of the treatment (Methods).

Changes in greenhouse gas (GHG) emissions from soils represent a further route to affecting the climate mitigation potential of the wollastonite treatment. Despite a rapid increase of one pH unit in the upper organic soil horizon (Oie), soil respiration CO_2 fluxes showed no significant difference between watersheds during the first 3 years after treatment (Groffman et al., 2006). However, our analysis of newly available longer-term datasets indicates that the treatment significantly reduced soil respiration in the high-elevation hardwood zone ($\sim$ 660–845 m a.s.l.) ($\chi^2(1,270) = 17.2$, $P < 0.001$), possibly due to reduced fine-root biomass (Fahey et al., 2016) rather than changes in microbial activity (Groffman et al., 2006). No significant effects on soil respiration were detected in any of the other HBEF vegetation zones (Fig. 3). The wollastonite treatment increased the soil sink strength for CH_4 ($\chi^2(1,266) = 30.8$, $P < 0.001$) in the low-elevation hardwood zone (482–565 m a.s.l.), while it decreased in the high-

elevation zone ($\chi^2(1,268) = 22.3$, $P < 0.001$) (Supplement, Fig. S8). There were no significant treatment effects on soil N_2O fluxes in any vegetation zone (Supplement).

3.5 Logistical CO_2 emissions and net CDR

We next considered carbon emissions (penalties) for logistical operations involved in mining, grinding, transporting, and applying the wollastonite (Fig. 4, Table 2). In the HBEF experiment, wollastonite was mined and milled on site near Gouverneur, New York. We used CO_2 emissions factors for electricity generation in upstate New York (United States Environmental Protection Agency, 1999) to estimate the maximum CO_2 penalty for mining and grinding to the mean particle size 16 μm diameter (Methods). However, local hydropower (Energy Information Administration, 1997) and regional nuclear power suggest these costs could have been zero. This would represent a substantial carbon saving for the overall ERW process relative to prior expectation of ERW studies in which grinding CO_2 emissions account for up to 30 % reduction in ERW–CDR efficiency (Renforth, 2012; Moosdorf et al., 2014).

In the HBEF experiment, the milled wollastonite was transported by highway to Allerton, Illinois, for pelletization and then returned to the staging area near Woodstock, New Hampshire (round trip > 3150 km). Transportation CO_2 emissions were 0.22–0.61 t CO_2 t Wo^{-1}. Given coal power in central Illinois, we estimate pelletization emitted up to 0.02 t CO_2 t Wo^{-1} (Methods). Application at Hubbard Brook occurred via 55 $\sim$ 5 km helicopter flights, which gives a further CO_2 cost of 0.01–0.15 t CO_2 t Wo^{-1}. In total, these lo-

Figure 4. Carbon penalties for the wollastonite treatment. Carbon penalties for logistic elements of the treatment are compared with literature estimates for large-scale roll-out of enhanced rock weathering for the HBEF treatment (3.44 t ha^{-1}), with and without long-distance transport for pelletization.

gistical operations emitted 0.23–0.69 t CO_2 t Wo^{-1} or 0.8–2.4 t CO_2 ha^{-1} for the 11.8 ha of the HBEF treated watershed (Table 4). However, local pelletization could have reduced heavy-duty vehicle (HDV) transport distance to ~ 400 km and lowered total CO_2 emitted during logistical operations to 0.04–0.15 t CO_2 t Wo^{-1}. At other forested sites, where wind-drift of material is not critical, pelletization may not be necessary.

Table 4. Measured elements of the treatment effect on the greenhouse gas budget for the Hubbard Brook Experimental Forest wollastonite experiment.

Equation (14)	Greenhouse gas sinks[a] and emissions[a] (t CO_{2e} ha^{-2})	Pessimistic	Optimistic
Ecosystem responses[b]			
Δwood	Wood production sink increased over 10 years[c]	8.946	9.542
ΔSRESP	Soil respiratory CO_2 emissions have reduced[a] since 2002	2.213	2.646
ΔCH4	Soil methane sink has increased since 2002	0.015	0.029
ΔN2O	Soil N_2O emissions since 2002 (no significant difference)	0	0
	Net ecosystem response at the treatment site through 2014	11.174	12.218
Downstream sequestration and emissions responses			
ΔCONS	CO_2 consumption sink through 2014 (Wo-CO_{2,HCO_3} and Wo-$CO_{2,Ca}$)	0.025	0.129
ΔNO3N2O	Downstream N_2O emissions[d] from treatment date through 2014	−0.071	−0.016
ΔDOC	DOC export emissions[d,e] from treatment date through 2014	−0.203	0
	Net downstream balance through 2014	−0.228	−0.129
Logistics:			
	Mining/grinding given hydro or nuclear/petroleum power	−0.162	0
	Helicopter ($\sim$ 55 5 km flights)	−0.051	−0.021
	HDV transport (New York to Illinois to New Hampshire)	−2.135	−0.787
	Pelletization (in Illinois, coal power)	−0.068	0
LOGPEN	Total logistical emissions	−2.416	−0.808
ΔGHG	Partial treatment effect on greenhouse gas balance	8.509	11.523

[a] Defined as the difference between watersheds: treated − reference for sinks and reference − treated for emissions. [b] Some possible treatment responses such as canopy respiration and particulate organic carbon export are unknown. [c] After Battles et al. (2014). We have not attempted to extrapolate these results. [d] ΔDOC and ΔNO3N2O are penalties because these lead to CO_2 and N_2O emissions downstream. [e] The "optimistic" value for DOC assumes complete burial and undesirable low-oxygen conditions in downstream waters.

These carbon emission penalties must be subtracted from watershed carbon removal to calculate net CDR for the wollastonite treatment at HBEF (Fig. 5; Table 4). Compared in this way, we find increased wood production over 10 years (Battles et al., 2014) repays the total logistical CO_2 costs 4–12 times over. The components (Fig. 5; Table 4) comprise 8.5–11.5 t CO_2 ha^{-1} of the total GHG budget associated with the wollastonite treatment (Methods). These figures would increase to 10.4–12.2 t CO_2 ha^{-1} if the wollastonite had been pelletized anywhere along the route from Gouverneur to New Hampshire.

Wollastonite treatment effects on stream-water chemistry play a minor role in the greenhouse gas budget (Fig. 5; Table 4). For our hypothetical 10-fold higher treatment (34.4 t ha^{-1}), CO_2 consumption calculated by assumed calcium release is $\sim$ 10 times higher, but carbon emission penalties scale with increased rock mass. Assuming pelletization near the mine to reduce transport costs, the total logistical penalty would be 1.2–5.1 t CO_2 ha^{-1}. In total, net CDR would be 6.8–12.4 t CO_2 ha^{-1} for the 10-fold larger treatment if none of the other GHG fluxes changed. We have not attempted to extrapolate other forest biomass and soil GHG fluxes or stream-water DOC and NO_3^- responses.

3.6 Potential for deployment at larger scales

The HBEF forests are representative of a major area of eastern North America receiving acid deposition since the 1950s (Likens and Bailey, 2014) which may be suitable for remediation and carbon capture via ERW treatment with a silicate rock or mineral. For example, the Appalachian and Laurentian-Acadian northern hardwood forests (NHWFs) covering a combined area of 0.137 Mkm^2 in the United States (Ferree and Anderson, 2013) have the same dominant hardwood trees as the HBEF experimental watersheds (*Fagus grandifolia, Betula alleghaniensis*, and *Acer saccharum*). Acid deposition exceeded "critical loads" likely to harm ecosystems in almost 9000 ha of New Hampshire's *Acer saccharum* stands (NHAs) (Schaberg et al., 2010). These forests might be expected to respond similarly to a wollastonite treatment. The acid-sensitive trees *Acer saccharum* and *Picea rubens* are also widely distributed along the high-elevation acid sensitive regions of the Appalachian Mountains which have already been impacted by acid deposition (Lawrence et al., 2015). We define this as a 40 km corridor along the Appalachian Mountains comprising 0.14 Mkm^2 and overlapping with the High Allegheny Plateau (HAL) ecoregion where *Acer saccharum* is declining above $\sim$ 550 m a.s.l. (Bailey et al., 2004) (0.07 Mkm^2).
Figure 5. Carbon responses for the wollastonite treatment. Elements of the greenhouse gas balance associated with the wollastonite treatment (Table 4). The CO_2 consumption range is given by Wo-CO_{2,HCO_3} calculated by Eq. (3) and Wo-$CO_{2,Ca}$ calculated by Eq. (4), time-integrated from the application date through 2014. Nitrate export in stream water leading to N_2O greenhouse gas emissions downstream and a small increase in the soil CH_4 sink have been converted to CO_2 equivalents (Methods). Exported DOC is assumed to be respired downstream.

We examined the potential CO_2 consumption for a range of wollastonite application rates encompassing those suggested for ERW strategies (Strefler et al., 2018; Beerling et al., 2018) (Fig. 6). In this analysis, we adjusted mean (2003–2012) Wo-$CO_{2,Ca}$ for the actual $3.44\,t\,ha^{-1}$ treatment ($\sim 0.2\,mol\,C\,m^{-2}\,yr^{-1}$) proportionally for 10–$50\,t\,ha^{-1}$ treatments. We assume logistical carbon penalties are minimized and balanced by forest biomass carbon sequestration responses to treatment. This analysis suggests net CDR potential of 0.3–$1.7\,Mt\,CO_2\,yr^{-1}$ along the Appalachian corridor, which is $2\,\%$–$12\,\%$ of New Hampshire state emissions ($13.8\,Mt\,CO_2$) in 2016 (Energy Information Administration, 2019). However, world wollastonite reserves (Curry, 2019) ($\geq 0.1\,Pg$) are insufficient to treat large areas of eastern North America at rates of 10–$50\,t\,ha^{-1}$, highlighting the requirement for alternative sustainable sources of silicate materials.

4 Discussion

Our analyses of wollastonite application at the HBEF provide a unique long-term (15 year) perspective on the whole watershed carbon cycle responses and net CDR by accounting for the associated CO_2 costs of logistical operations. By 2015, net CDR amounted to 8.5–$11.5\,t\,CO_2\,ha^{-1}$ at a low rate of wollastonite application, with increased carbon sequestration into forest biomass playing the dominant role. We estimate that if the HBEF application rates were increased 10-fold, net CDR would increase by $8\,\%$, assuming $400\,km$ transport
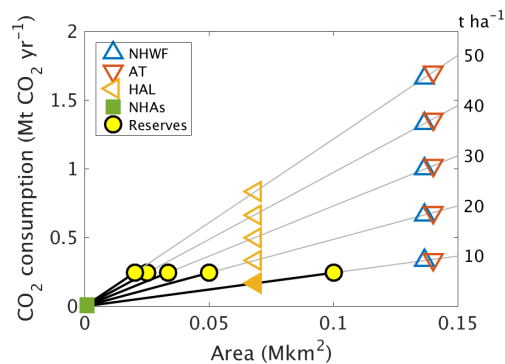

Figure 6. Projected CO_2 consumption following higher-dosage treatments. We considered the possibility of higher-dosage silicate treatments on other northeastern United States higher-altitude forests affected by acid rain, such as *Acer saccharum* forests in New Hampshire (NHAs), the High Allegheny Plateau (HAL) ecoregion, the Appalachian trail corridor (AT), or northern hardwood forests (NHWFs) dominated by the same tree species as at Hubbard Brook. Because the world's wollastonite reserves (yellow discs) are insufficient to treat these areas, other calcium-rich silicate minerals would be required. CO_2 consumption due to higher dosage ($t\,ha^{-1}$) is estimated as (mean observed $CO_{2,Ca}$ between 2004 and 2012) $\times$ area $\times$ dosage / $3.44\,t\,ha^{-1}$.

distances and no change in forest responses. Amplification of organic carbon capture may therefore represent a major CDR benefit of ERW when applied to forested lands affected by

acid rain. Forest management practices, disturbance regimes, and the ultimate fate of any harvested wood are also important in determining the storage lifetime of the sequestered carbon. Our results highlight the need to carefully monitor the net carbon balance of forested ecosystems in response to a silicate treatment, including wood and canopy respiration (Fahey et al., 2005) (Methods). This challenging goal might best be achieved with fully instrumented eddy covariance plots, although the HBEF topography is not well suited for this approach (Fahey et al., 2005).

Inorganic CO_2 consumption calculated based on streamwater bicarbonate fluxes approximately doubled in the treated watershed relative to the reference watershed 15 years post-treatment (0.028 and 0.016 t CO_2 ha^{-1} respectively) (Table 3). The presence of SO_4^{2-}, NO_3^-, and organic acid anions lowered the efficiency of CO_2 consumption by alkalinity generation, with acid deposition having the single largest calculated effect (Table 3). The cause of increased NO_3^- export from the treated watershed is not as yet understood (Rosi-Marshall et al., 2016). If it proves a general feature of terrestrial ecosystem responses to silicate mineral treatment, this could affect the efficiency of carbon capture via bicarbonate export. Overall, we suggest that continued recovery of eastern North American and European forests and soils from acid deposition creates conditions beneficial to watershed health, carbonic-acid-driven weathering, and inorganic carbon export following application of crushed silicate minerals.

In Asia, acid rain is an ongoing problem with an estimated 28 % of Chinese land area ($\sim$ 2.7 Mkm^2) receiving potentially damaging S deposition in 2005 (Zhao et al., 2009), and critical loads were exceeded in $\sim$ 0.36 Mkm^2 of the European Economic Area (EEA) in 1999 (Larssen et al., 2003), approximately double the affected area of US northern hardwood forests (Fig. 6). Figure 6 suggests that a single 30 t Wo ha^{-1} treatment over 0.14 Mkm^2 (Appalachian Trail corridor) could, in principle, sequester $\sim$ 1 Mt CO_2 yr^{-1} or 15 Mt CO_2 over 15 years via wollastonite-derived Ca export in stream water alone. Adding the Chinese and European acidified areas could potentially sequester 0.34 Gt CO_2, approximately 0.2 %–0.7 % of the $\sim$ 50–150 Gt CDR required by 2050 to avoid warming in excess of 1.5° (Rogelj et al., 2018). Inclusion of biomass and soil responses increases CDR contributions from ERW on acidified forests, but these will still be modest. Assuming no further forest responses beyond the 15-year HBEF timeframe, we report a GHG balance of $\sim$ 10 t CO_{2e} ha^{-1}. This translates to 1 Gt CO_{2e} Mkm^{-2} suggesting 3.2 Gt CO_{2e} over 15 years for the Appalachian Trail, the EEA, and China combined, or 2 %–6 % of global required CDR as described above.

It is uncertain whether other acidified forest ecosystems would respond similarly to the HBEF *Acer saccharum* forests in New Hampshire. Many Chinese soils (Duan et al., 2016), as well as old deep soils in areas such as the Virginian Blue Ridge Mountains and the German Harz and Fichtel

mountains (Garmo et al., 2014), have high SO_4^{2-} sorption capacity. These soils may retain substantially more SO_4^{2-} than the HBEF soils, with potential for prolonged SO_4^{2-} flushing following ERW treatment and lower bicarbonate production. Liming studies suggest a range of other effects, some of which may also occur with silicate treatments. Liming increases nitrate export, migration of heavy metals and acidity to deeper soil, and fine root production in topsoils leading to frost damage (Huettl and Zoettl, 1993).

Many forests have been limed with carbonate minerals such as calcite and dolomite to mitigate acidification in the past. Dolomite has also helped reverse Mg deficiency in conifers (Huettl and Zoettl, 1993). Liming generally improves water quality, although it also forms mixing zones with high-molecular-weight Al complexes toxic to fish (Teien et al., 2006). With silicate treatments, nontoxic hydroxyaluminosilicates form instead (Teien et al., 2006). Unfortunately, carbonates are contraindicated for CDR on acid soils because they can be a net source of CO_2 in the presence of strong acids (Hamilton et al., 2007). Treatments of European and North American acidified forests with calcite (1–18 t ha^{-1} $CaCO_3$) or dolomite (2–8.7 t ha^{-1} $CaMg(CO_3)_2$) have, in general, resulted in increased DOC export and soil respiration without increasing tree growth, regardless of forest composition (Lundström et al., 2003). As calcite and dolomite are 44 % and 48 % CO_2 by weight, these treatments will have released 0.44–7.9 and 0.96–4.54 t CO_2 ha^{-1} respectively when fully dissolved, although dissolution may be slow. Over 6 years following a 2.9 t dolomite ha^{-1} treatment (90 % 0.2–2.0 mm grains) in a Norwegian coniferous watershed equating to 1.36 t CO_2 ha^{-1}, less than 1 % of the dolomite dissolved (Hindar et al., 2003). We estimate that CO_2 consumption corrected for CO_2 release and as measured with dolomite-derived Ca and Mg in stream water (Dol-$CO_{2,Ca+Mg}$) averaged 0.02 mol CO_2 m^{-2} yr^{-1}. CO_2 release from carbonate minerals equals Ca and Mg release on a molar basis, so 0.02 mol Dol-CO_2 m^{-2} yr^{-1} was also either exported in stream water or lost to the atmosphere. This experiment may have a negative greenhouse gas balance depending on logistical penalties and soil respiration, as there was no significant treatment effect on tree growth or vitality (Hindar et al., 2003). Ca-sensitive *Acer saccharum* is present at Woods Lake in New York state, yet tree biomass decreased with no significant differences relative to reference catchments during the 20 years following a 6.89 t Mg-calcite ha^{-1} application (Melvin et al., 2013), equivalent to 3.07 t CO_2 ha^{-1} given 8 % Mg content of the pellets. In contrast to our study and other liming studies, root biomass and soil carbon stocks increased in response to this treatment, although soil respiration was reduced (Melvin et al., 2013). *Acer saccharum* basal area and crown vigour increased over 23 years in response to 22.4 t dolomitic limestone ha^{-1} (equivalent to 10.0 t CO_2 ha^{-1}) on the Allegheny Plateau, although basal area and survival of another domi-

nant canopy species, *Prunus serotina*, was reduced (Long et al., 2011). Clearly, forest responses to mineral treatments are species- and site-specific.

Although the HBEF experiment used wollastonite, this is not a target mineral for ERW, because of both its limited reserves (Curry, 2019) and high monetary costs (Schlesinger and Amundson, 2018). Recent all-inclusive guide prices of $\sim \text{USD} \, 700 \, \text{Mg}^{-1}$ for helicopter deployment of pelletized lime along the Appalachian Mountain corridor are comparable to the price of $\text{USD} \, 694 \, \text{Mg}^{-1}$ for unpelletized $10 \, \mu\text{m}$ wollastonite in 2000 (Virta, 2000). Less expensive materials such as locally sourced waste fines from mines or volcanic ash (Longman et al., 2020) should be considered if their heavy metal content is low, but the choice of treatment material should be considered together with the vegetation and the native minerals. Application of magnesium-rich materials (e.g. olivine), for example, may help reverse Mg deficiency in *Pinus sylvatica* and *Picea abies* as dolomite has done (Huettl and Zoettl, 1993), but some other tree species, such as *Acer saccharum*, have a higher demand for calcium than for magnesium (Long et al., 2009). The treatment of ecologically sensitive catchments always requires caution as some species, such as *Sphagnum* mosses and lichens, may respond poorly to treatment (Traaen et al., 1997).

Finally, we consider integration of ERW treatments with forest management practices. Dominant CDR pathways depend on biogeochemical cycling which in turn depends on the life cycle of the dominant trees. For example, base cation export and therefore CO_2 consumption temporarily increases following clear-felling, then decreases while trees are young and growing due to base cation uptake, and remains low after trees mature due to nutrient recycling (Balogh-Brunstad et al., 2008). These dynamics may be less obvious in forests which are not clear-felled; *Acer saccharum* forests are often thinned and retain a canopy as the seedlings are adapted to shade. Individual *Acer saccharum* trees can live for over 300 years, growing relatively slowly for the first 40 years and attaining maximum height during the first 150 years (Godman et al., 1990). One may expect to maximize wood production of growing trees with ERW treatments meeting or exceeding the forest demand for previously limited nutrients such as calcium, which would also minimize soil respiration if the trees allocate less carbon to roots. Treatments could be repeated as necessary to meet the nutritional needs of sensitive trees or to maintain high CO_2 consumption. Conversely, rising soil pH may not suit some species. For example, *Acer saccharum* normally grows in organic-rich soils with pH under 7.3 (Godman et al., 1990) and its growth may be hindered at higher pH following large treatments. Outside the main tree growth phase, and in forests without responsive tree species, CO_2 consumption could become the dominant GHG response to ERW treatments depending on the extent to which it is counteracted by DOC export as soil pH rises (Johnson et al., 2014) and decomposition rates and fluxes rise (Lovett et al., 2016). Site-specific research is required to determine the optimum dosage, timing, efficacy, and suitability of ERW treatments on acid-impacted forests.

Appendix A: Contributions of rain and snow precipitation to stream-water chemistry

We estimated the contribution of rain and snow (Likens, 2016b, a) relative to all other sources using a previously published mixing model (Négrel et al., 1993). We assume all Cl^- in the water is from rain and snow, noting however that this common treatment of Cl as an unreactive tracer is not always justified (Lovett et al., 2005). We calculate the contribution of precipitation to the stream water (α_{rain}) using Na and Cl, which are less affected by nutrient cycling and adsorption than other major ions (Négrel et al., 1993):

$$\alpha_{rain,Na}(t) = \frac{\left[\frac{Cl}{Na}\right](stream, t)}{\left[\frac{Cl}{Na}\right](rain, t)}. \tag{A1}$$

To account for attenuation of the rain and snow precipitation leaching through the soil, Cl/Na and HCO_3/Na at any given time (t) are means from the previous 3 months. We estimate the contribution of rain and snow to other ions such as HCO_3^- in the stream water as follows:

$$\alpha_{rain,HCO_3}(t) = \alpha_{rain,Na}(t) \times \frac{\left[\frac{HCO_3}{Na}\right](stream, t)}{\left[\frac{HCO_3}{Na}\right](rain, t)}. \tag{A2}$$

Appendix B: Fraction of calcium derived from wollastonite

We applied an existing two-component mixing model (Peters et al., 2004):

$$X_{Ca}(t) =$$

$$\left[\frac{\left(\left(\frac{^{87}Sr}{^{86}Sr}\right)_{post} - \left(\frac{^{87}Sr}{^{86}Sr}\right)_{pre}\right)\left(\frac{Sr}{Ca}\right)_{pre}}{\left(\left(\frac{^{87}Sr}{^{86}Sr}\right)_{post} - \left(\frac{^{87}Sr}{^{86}Sr}\right)_{pre}\right)\left(\frac{Sr}{Ca}\right)_{pre} + \left(\left(\frac{^{87}Sr}{^{86}Sr}\right)_{Wo} - \left(\frac{^{87}Sr}{^{86}Sr}\right)_{pre}\right)\left(\frac{Sr}{Ca}\right)_{Wo}}\right], \tag{B1}$$

where pre-app and post-app refer to pre-application and post-application stream-water concentrations and Wo refers to wollastonite. The Sr data (Blum, 2019) have been extended through 2015 (Fig. S1a). See Supplement for further discussion of the use of strontium and its isotopes as tracers of Ca^{2+} provenance.
